A u-blox GNSS receiver for orienteering mapping

Libor Pecháček
January 2019

Abstract

This document describes a GNSS receiver designed for orienteering mapping and experience gained from this endeavor. The author is neither expert in electrical design nor expert on geography and satellite navigation systems. The text is intended to provide view into consumer grade electronics commonly used in orienteering and as a hint about future development directions.

Introduction

My use of GNSS receiver for map making started inconspicuously during a map revision for a club training. I was mapping a newly harvested area with tracks and fences with the traditional take-azimuth-pace-draw-on-paper methodology. However, I had a GPS data logger in my pocket. Later at home I put my scanned forest original together the GPS trace and saw that many of the lines overlap. That led me to trying out a tablet together with the GPS logger on a 4 km^2 map. The results were satisfactory in terms of position accuracy. However, and that was an important for the future

experiments, the tablet occasionally failed to establish connection with the logger. I opened the logger case to see if there is something obvious to fix inside. Needless to say that I didn't see anything but I learned about how the device design. Later I tried out a GPS+GLONASS receiver and saw that it does not bring additional accuracy in my terrain. At least that drew my attention towards multi-constellation GNSS receivers. In summer 2018 I heard the news that the European Galileo navigation system is nearing completion with four additional satellites being launched into their orbits. That sparked my interest in how would a GPS+GLONASS+Galileo receiver behave.

Hardware design

The data logger case

As said earlier, I was using Canmore GT-750FL data logger for my field work and that my tablet occasionally failed to establish Bluetooth connection to the receiver. I was interested to see if there is perhaps some trivial problem in it that I can fix and get the data logger work reliably.

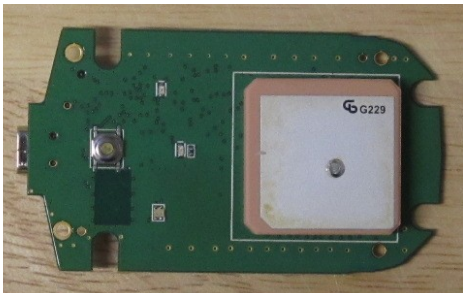

Figure 1: Canmore GT-750FL board – top side

Upon removing the fours screws which hold the device together the electronic board appeared. On one side there is receiver antenna, the common ceramic patch type, indicator LED's and power button. On the other side there is all the magic I was looking for.

At first glance it looked like complex device but after a few tens of minutes of staring at the board, and looking up the chip specifications, the design stood out. On he left there are battery charger and voltage stabilizer circuits and Bluetooth communication module. On the right there are GPS receiver circuit and processor taking care of the data logging function.

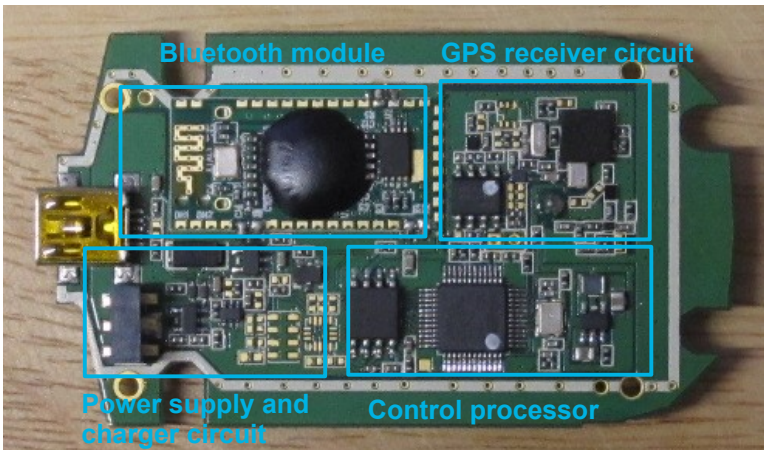

Figure 2: Canmore GT-750FL board – bottom side

The GPS chip is SiRFstar IV, contrary to product documentation. The processor is an ST Microelectronics STM32 micro controller with additional flash memory for data log.

The Bluetooth module does not have any marking but the important point is that is it is soldered on top of the board and connects at only six points. The observation is that the Bluetooth function is isolated into a standard looking module which might be possible to get separately.

Figure 3: Bluetooth module sitting on the board.

Overall, the lesson learned was that a Bluetooth receiver usable for fieldwork consists of a GNSS receiver, Bluetooth communication module and a control processor which is somehow passing data between the two.

Galileo

With the news about four more Galileo satellites being guided to their orbits, I felt the craving for trying out the Galileo system. At the time I could not find a commercial receiver for a price I would pay for an experiment so I started looking for discrete components to combine into a usable device. I was looking for Bluetooth serial port module, a small and easily programmable micro controller and a Galileo capable GNSS receiver. Starting at AliExpress I gathered all the components after a few hours of research. I bought a "*Bluetooth 4.0 For Arduino Android IOS HM-10 BLE CC2540 CC2541 Serial Wireless Module*", "*STM32F103RCBT6 Maple Mini ARM Cortex-M3 leaflabs Leaf Controller Board Module 3.3V For Arduino STM32*" and "*UBLOX Micro GPSV5 NEO-M8N GPS Module GNSS HMC5983 SAW LNA Triple Band Antenna ANT*". As an extra I added "*0.96 inch IIC Serial Yellow Blue OLED Display Module 128X64 I2C SSD1306 12864 LCD Screen Board GND VCC SCL SDA 0.96" for Arduino*" for the possibility of displaying data from the micro controller.

All the components arrived quickly into my home and I started experimenting. I knew that the GNSS module has serial line output so I focused on the Bluetooth part to get the data into my tablet. I took the "Android Bluetooth 4.0 serial wireless module" and paired it with the tablet. Pairing worked but data didn't flow into Bluetooth GPS application. Experts likely have smile on their face now. The point is that Bluetooth 4.0 Low Energy (BLE) standard does not specify the serial port service which all the data loggers use for moving bits into Android devices. The correct service is Bluetooth 2.0 RFCOMM, governed by Serial Port Profile (SPP) specification. Back to web browser and search for Bluetooth RFCOMM module. HC-06 seems to be an established product for this purpose.

The HC-06 module did far much better. However, still I spent a few hours making it work. The product documentation is somewhat superficial and the product behavior diverges at a few points. The main hurdle was making the clone listen to configuration commands sent over the serial line. Typically such devices listen to so called AT-commands. After sending "AT" followed by enter key they respond with "OK". This one did not. The trick was to send "AT" as one string, i.e. not two consecutive characters, *without* the carriage return character generated by enter key. After figuring this out it was easy to program the unit to my needs.

Then there was the GNSS receiver. I was careful to buy a genuine u-blox receiver and not one of the clones. That move paid off in availability of documentation and the device behaving to the specs. I was even surprised that there is u-Center software for configuring and testing u-blox chips. It took a while to wrap my head around the configuration mechanism and find all the tunables that enable Galileo system reception and reporting but in the end I succeeded to receive GPS+GLONASS+Galileo at my kitchen table! At this point I had NMEA data from the receiver and could move them to the Android Bluetooth GPS application for further processing.

Next I looked into the power system to make the receiver portable. All the components operate at 3.3 V. I also had some flat Lithium rechargeable battery cells from a laptop. Thankfully, battery protector and charger modules are easy to get at the local electronics shop so I bought them, together with a voltage stabilizer for the Bluetooth module and battery status display. The design shaped up. Connect the battery cell, whose voltage slides from 4.2 V down to 2.8 V as it discharges, to the battery side of the charger module. From the device side of charger module current goes via power switch and battery monitor to the GNSS module and via voltage stabilizer to the Bluetooth module. As the last step, connect the GNSS module serial line directly to the Bluetooth module serial port. The micro controller I bought is not necessary as both the modules retain their configuration and there is no need for power-up initialization.

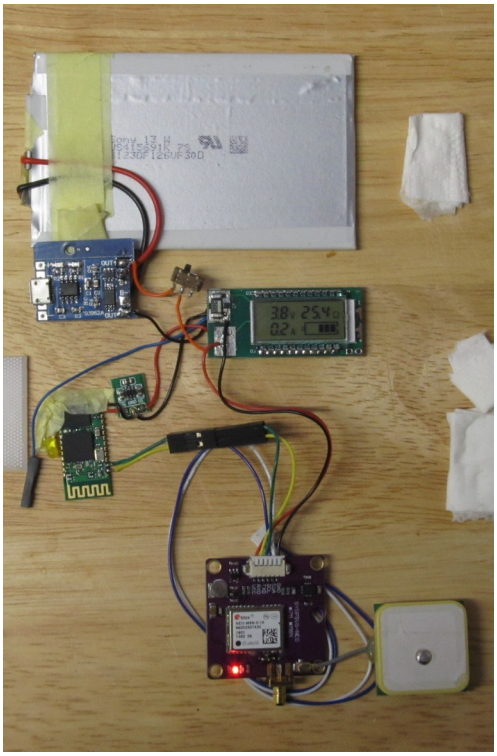

Figure 4: u-blox based Bluetooth GNSS receiver

The above is a working Bluetooth GNSS receiver. Given the choice of components, it can work even without additional component configuration. The u-blox GNSS module sends data at 9600 baud and the HC-06 Bluetooth module also operates at 9600 baud. However, to fully utilize the GNSS chip capabilities, it is advisable to raise the inter-component communication speed to 38400 baud. Higher speeds, however, make trouble in my circuit as the Bluetooth module seems incapable to reliably operate at fast pace.

After all the components were connected (soldering skills are required), the device needed to get some mechanical robustness. I placed everything atop the Li-Ion cell and separated the larger components from the cell with folded paper tissues.

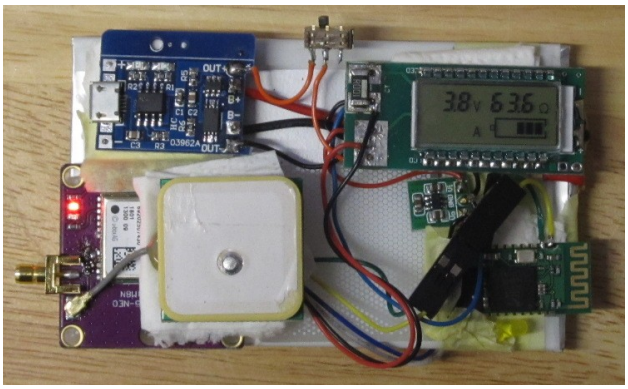

Figure 5: All components placed atop the Li-Ion battery

Especially the charger circuit emits a lot of heat during charging which should not transfer into the cell. Also the sharp module board edges should not touch the cell surface as Li-Ion cells are sensitive to damage and can catch fire under certain circumstances. When the components were in correct positions, I fixed them with painter's tape. The device can be made waterproof by placing it in a plastic zip bag. Please note that the gold plated antenna connector on the GNSS module is not part of AliExpress delivery.

KISS at work

KISS is a popular engineering principle, often being transcribed as "Keep it simple stupid". The common wisdom behind the words is that simpler systems tend to work better than complicated ones. What could be simplified about the above design?

1. Antenna
   The GYGPSV5 module board gets delivered with active antenna. The point of amplifier in

active antenna is cover signal losses on the path from antenna to the receiver. With about 5 centimeters of cable between antenna and the board amplifier just adds noise. Passive antenna will do.

2. Power system
   Few people have Li-Ion cells in their drawer. There is no point to assemble the power system from discrete parts. Use power bank as the source.

3. Bluetooth module
   Making the HC-06 clone work consumed an enormous amount of time. Later reconfiguration was equally painful. Use well documented components from reliable suppliers.

Bluetooth GNSS receiver – take 2

With the lessons learned earlier I bought second set of components. This time it was Drotek's *Ublox NEO-M8N GPS module* (Drotek is u-blox's technology partner) and SparkFun's *SparkFun Bluetooth Modem - BlueSMiRF Silver*. BlueSMiRF Silver is a Class 2 Bluetooth device with 2.5 mW transmission power, which is enough for this device. Both devices can be powered from 5 V supply. The Drotek GNSS module has both serial and USB connection and comes with a cable that has Dupont connectors at one end.

Figure 7: Drotek GNSS module with cable

The SparkFun Bluetooth module has holes ready for a pin header that can connect to the Drotek cable. This is the only soldering needed in this design and a local electronics repair shop can do the soldering for you.

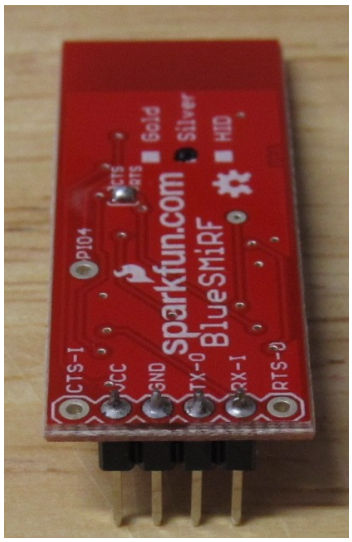

Figure 8: BlueSMiRF Silver module after soldering the pin header

As part of the soldering RTS and CTS pads, clearly marked on the board, should be shorted. This is a recommendation from the module vendor for the type of connection we are going to use.

Now that the pin header is in place, the devices can be connected. The six-wire cable from Drotek module uses four wires and their connections are marked on the board. First wire in the flat cable (marked with color strip) is the ground. Connect it to the GND pin on the Bluetooth module. GNSS module 5V goes to VCC on Bluetooth module. Now the communication lines are crossed. Transmit pin of one module is connected to receive pin on the other module. Connect TX from one module to RX on the other one and vice versa.

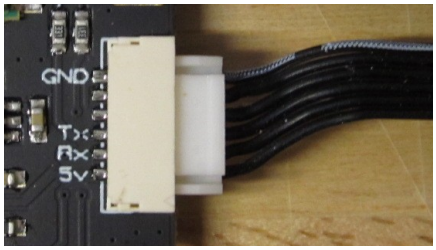

Figure 9: Connector markings on the GNSS module

This completes the connection between the modules. Double check that GNSS module's GND and 5V go to GND and VCC on the Bluetooth module as well as TX on one side goes to RX on the other. After this the device is ready for programming.

The only essential step is the change of GNSS module serial line speed from the default 9600 baud to 115200 baud which is the Bluetooth module setting. Do it with the u-Center software after connecting the GNSS module with USB cable to your computer.

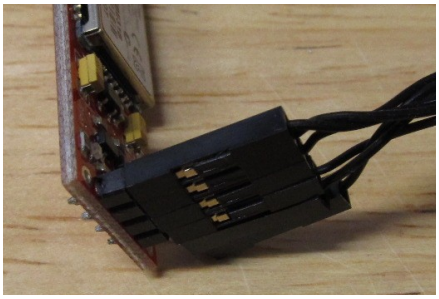

Figure 10: Cable connection to the Bluetooth module - two wires are unused

After plugging the USB cable into computer the blue power LED on GNSS module will light and red stat LED will blink. The GNSS module will appear as a new COM port in Windows. Refer to u-Center documentation for instructions on how to connect the module and work with the software. The port settings can be found under UBX-CFG-PRT message. Change UART 1 baud rate to 115200 and save the configuration to non-volatile memory with UBX-CFG-CFG where you choose *Save current configuration* option.

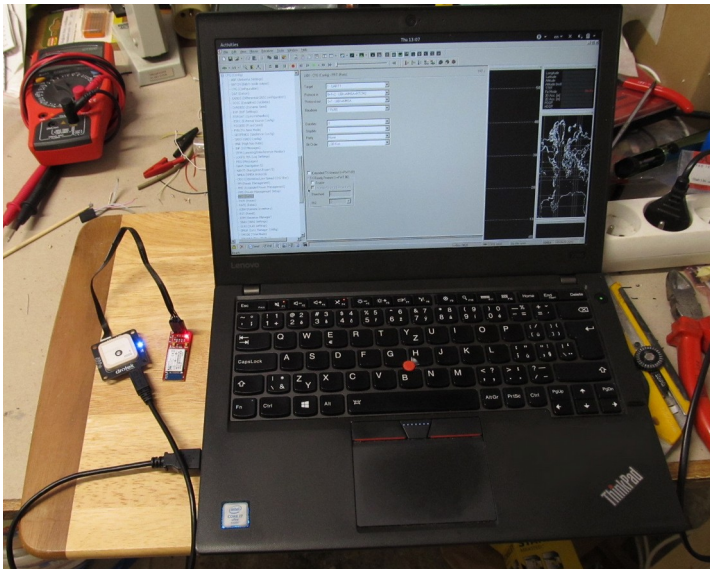

Figure 11: Programming the GNSS module

At this point you should be able to connect your Android device with the Bluetooth module and see NMEA messages in the Bluetooth GPS application log window. If it's not the case, check serial port in the configuration and re-check the cable connections.

As mentioned earlier, the device can be made portable by connecting it to a power bank. I had some small one in my drawer. You may opt for a flat model which can better fit into pocket. After applying a few paper tissues for insulation and a bit of painter's tape the device is ready for a trip.
